1 Introduction

prova¹ Alexakis 2023.

2 Theoretical background

The primary focus of this work is the integration of the incompressible Navier-Stokes equations with a random forcing term:

$$\partial_t \mathbf{u} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\nabla p + \nu \Delta \mathbf{u} + f_0 \mathbf{f} \quad (2.1)$$

$$\nabla \cdot \mathbf{u} = 0 \quad (2.2)$$

where \mathbf{u} is the velocity field, p is the pressure, ν is the kinematic viscosity, and \mathbf{f} is a random forcing term. For the sake of clarity and simplicity the amplitude factor f_0 of the forcing have been taken out from the force itself. The second equation is called *incompressibility condition* and it translates the fact that the fluid cannot be compressed. The forcing term is chosen to be Gaussian for the vorticity formulation, which is detailed below. Throughout the project the density of the fluid is assumed to be constant and equal to 1.

2.1 Stream function formulation

In Batchelor 2000, a new variable is introduced in order to simplify the integration of the 2D incompressible Navier-Stokes equations. This quantity, called *stream function* and denoted by ψ , is defined as the flow rate across a given line. More accurately, if \mathcal{C} is a curve joining two points O (fixed) and $P = (x, y)$, the stream function streams function a function f the coordinates of the point P is then

$$\psi(x, y) - \psi_0 = \int_{\mathcal{C}} \mathbf{u}^\perp \cdot d\mathbf{s} = \int_O^P -v dx + u dy \quad (2.3)$$

where $\mathbf{u} = (u, v)$ is the velocity field, $d\mathbf{s} = (dx, dy)$ is the tangent vector to the curve, and ψ_0 is a reference value. In differential form, it can be written as

$$d\psi = -v dx + u dy = \frac{\partial \psi}{\partial x} dx + \frac{\partial \psi}{\partial y} dy \quad (2.4)$$

where the last equality follows from the exact differential property. Thus, one obtain the following useful relations:

$$u = \frac{\partial \psi}{\partial y} \quad \text{and} \quad v = -\frac{\partial \psi}{\partial x} \quad (2.5)$$

¹This is a footnote.

Note the arbitrary choice of \mathbf{u}^\perp in the definition of the stream function. In the present work, the choice is made to be $\mathbf{u}^\perp = (-v, u)$, in order to keep the same sign convention as in similar works (Boffetta and Ecke 2012; Alexakis and Biferale 2018). The formulation with the alternative stream function $\psi' := -\psi$ is sometimes used in other fields of fluid dynamics, mostly in meteorology and oceanography.

Note that using this definition, the incompressible condition $\nabla \cdot \mathbf{u} = 0$ is automatically satisfied. Finally, introducing the scalar vorticity $\omega := \nabla \times \mathbf{u} = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} = -\Delta\psi$, one can rewrite the Navier-stokes equations in terms of the vorticity:

$$\partial_t \omega + (\mathbf{u} \cdot \nabla) \omega = \nu \Delta \omega + f_0 f_\omega \quad (2.6)$$

$$\nabla \cdot \omega = 0 \quad (2.7)$$

where the rotational has been taken to both sides of Eqs. (2.1) and (2.2) and some basic vector have been used. The main objects of interest in the vorticity formulation are the *vortices*, which according to Saffman 1993 are the local regions on the plane with non vanishing vorticity and surrounded with an irrotational flow.

Now, using the relation between the stream function and the vorticity one obtains:

$$\partial_t \psi + \Delta^{-1}(\mathbf{u} \cdot \nabla) \Delta \psi = \nu \Delta \psi + f_0 f_\psi \quad (2.8)$$

The reader may quickly notice that this equation seems more complicated than the first one. However, when transforming the equation to Fourier space, it becomes much more simpler (see Eq. (2.13)), with the advantage of having a scalar function as the main unknown variable and removing the incompressible condition.

The forcing term is assumed to be Gaussian, in particular it is taken of the form:

$$f_\omega(x, y) = \sum_{i=1}^{10} A_i \exp\left(-\frac{k_\ell^2}{2} [(x - x_{i,1})^2 + (y - y_{i,1})^2]\right) - A_i \exp\left(-\frac{k_\ell^2}{2} [(x - x_{i,2})^2 + (y - y_{i,2})^2]\right) \quad (2.9)$$

With this forcing we are introducing 10 pairs of vortices with opposite vorticity in a non-homogeneous way which a priori may introduce a nonzero momentum to the system. To correct that, we set the first Fourier coefficient to zero once we transform the forcing term to Fourier space. This implies that the actual force differs up to a constant factor from the one given above. The quantities A_i follow a uniform distribution between 0 and 1; k_ℓ quantifies the size of the vortices (thought in Fourier space) so that the vortices injected have size $\sim 1/k_\ell$, and the coordinates $x_{i,k}$, $y_{i,k}$, for $k = 1, 2$ are random variables that position the vortices inside a small disk of radius k_r centered at the origin such that the density of vortices is (almost) constant. To be more clear, if we express the coordinates of the vortices in polar coordinates, the angular variable is uniformly distributed between 0 and 2π and the radial variable follows a distribution $\sqrt{\mathcal{U}(0, \pi/k_r)}$ where $\mathcal{U}(a, b)$ is the uniform distribution between a and b . Indeed, one can easily check that the probability of finding a vortex inside a disk of ring $(r - dr, r)$ does not depend on r :

$$\mathbb{P}(r - dr < \sqrt{\mathcal{U}(0, \pi/k_r)} \leq r) = \int_{(r-dr)^2}^{r^2} \frac{1}{\pi/k_r} ds \simeq Cr dr + \mathcal{O}(dr^2) \quad (2.10)$$

Thus, since the area of the ring $\{(x, y) \in \mathbb{R}^2 : r - dr < \sqrt{x^2 + y^2} \leq r\}$ is proportional to $r dr$ at first order, the density of vortices is constant up to a small error of order dr .

The amplitude of the forcing is controlled by the parameter f_0 , which is chosen in such a way to keep the injection rate of energy constant and equal to 1. Because of that it has an implicit dependence on time, as explained below.

Forward-transforming f_ω to Fourier space, from the relation $\omega = -\Delta\psi$, one can easily get $\widehat{f_\psi}$ by dividing by k^2 each component of $\widehat{f_\omega}$.

2.2 Fourier space

The *Fourier transform* (FT) of a function $f : \mathbb{R}^2 \rightarrow \mathbb{R}$ is defined as

$$\widehat{f}(\xi) = \int_{\mathbb{R}^2} f(x) e^{-i\xi \cdot x} dx \quad (2.11)$$

for all $\boldsymbol{\xi} \in \mathbb{R}^2$ and its discrete version (DFT) for a square domain with N points in each direction is

$$\widehat{f}(\mathbf{k}) = \sum_{\mathbf{n} \in \mathbf{N}} \mathbf{f}_{\mathbf{n}} e^{-i\mathbf{k} \cdot \mathbf{f}_{\mathbf{n}}/N} \quad (2.12)$$

where $\mathbf{N} = \{0, 1, \dots, N-1\}^2$ is the set of points in the Fourier grid, $\mathbf{f}_{\mathbf{n}}$ is the value of the function in the physical space at the point \mathbf{n} , and $\mathbf{k} = (k_x, k_y)$ is the wave vector.

Taking the Fourier transform on both sides of Eq. (2.8) and using the well-known properties of the Fourier transform, one obtains:

$$\frac{d}{dt} \widehat{\psi} - k^{-2} \widehat{(\mathbf{u} \cdot \nabla) \Delta \psi} = -\nu k^2 \widehat{\psi} + \widehat{f_{\psi}} \quad (2.13)$$

where $k := |\mathbf{k}|$. Note that the non-linear term in the above equation has not been simplified. This is because in the simulation that term is backward-transformed to the physical space, computed, and then transformed back to the Fourier space, as it is less expensive than computing the non-linear term in Fourier space.

2.3 Reynolds number

The Reynolds number is a dimensionless quantity that characterizes the ratio of inertial forces to viscous forces in a fluid. It is usually defined as $\text{Re} := UL/\nu$, where U is a characteristic velocity of the flow, L is the characteristic length scale associated to it and ν is the kinematic viscosity. In the cases where there is no control on the injection velocity, but on the rate of energy injection ϵ , this equation is not useful anymore. To derive an alternative equation, the scaling theory of Kolmogorov is used (Frisch 1995). Let $\epsilon_{\ell} \sim u_{\ell}^2/\tau_{\ell}$ be the rate of change of energy at the scale ℓ , where u_{ℓ} is the velocity at that scale and τ_{ℓ} is the characteristic time at that scale. Using that $\tau_{\ell} \sim \ell/u_{\ell}$, one obtains $\epsilon_{\ell} \sim u_{\ell}^3/\ell$. Assuming that the energy transferred from the scale ℓ to smaller scales is the same as the energy received by the scale ℓ from larger scales (that is, the flux of energy across scales is constant), one obtains that the value ϵ does not depend on L and moreover $\epsilon \sim U^3/L$, i.e. $U \sim (\epsilon L)^{1/3}$. Thus, we get a new formula for the Reynolds number:

$$\text{Re} = \frac{\epsilon^{1/3} L^{4/3}}{\nu} \quad (2.14)$$

In the present work, the length scale L is determined by the size of the vortices injected in the disk, which in this case is $L = 1/k_{\ell}$. The injection rate of energy is determined by the forcing term, as follows. The amplitude f_0 is time dependent and is chosen in such a way that f_0^2 is the rate at which energy is injected per unit of area in the domain. More precisely, the amplitude of the forcing is taken as $f_0/\sqrt{0.5E_f\Delta t}$, E being the total kinetic energy of $\widehat{f_{\psi}}$, that is:

$$E_f = \sum_{\mathbf{k} \in \mathbf{K}} |\widehat{f_{\psi}}(\mathbf{k})|^2 k^2 \quad (2.15)$$

To check that indeed that is the case, at time t and time step Δt one has:

$$\widehat{\psi}(\mathbf{k}, t + \Delta t) - \widehat{\psi}(\mathbf{k}, t) = \Delta t G(\widehat{\psi}) + \sqrt{\Delta t} \frac{f_0}{\sqrt{0.5E_f\Delta t}} \widehat{f_{\psi}}(\mathbf{k}) \quad (2.16)$$

Here G refers to the non-linear term and the viscous term in Eq. (2.13). Multiplying by k , squaring the equation and summing over \mathbf{k} , one obtains:

$$\sum_{\mathbf{k} \in \mathbf{K}} k^2 \widehat{\psi}(\mathbf{k}, t + \Delta t)^2 - k^2 \widehat{\psi}(\mathbf{k}, t)^2 = \Delta t \cdot f_0^2 \frac{\sum_{\mathbf{k} \in \mathbf{K}} |\widehat{f_{\psi}}(\mathbf{k})|^2 k^2}{0.5E_f} + \mathcal{O}((\Delta t)^{3/2}) = 2\Delta t \cdot f_0^2 + \mathcal{O}((\Delta t)^{3/2}) \quad (2.17)$$

Dividing by $2\Delta t$ and taking the limit $\Delta t \rightarrow 0$, one obtains the rate of energy on the domain (per unit of area, as the density implicit in the equation) on the left hand side and f_0^2 on the right hand side. The interest is though in taking ϵ as the rate of energy per unit of area of the perturbation region. Thus, the desired formula is

$$\epsilon = f_0^2 \frac{4\pi^2}{\pi(\pi/k_r)^2} \quad (2.18)$$

and consequently the Reynolds number becomes:

$$\text{Re} = \frac{\left(f_0^2 \frac{4k_r^2}{\pi}\right)^{1/3} k_{\ell}^{-4/3}}{\nu} \quad (2.19)$$

2.4 Point-vortex model

The study has accomplished another simulation, far from the Navier-Stokes equations, but aiming to obtain qualitatively and quantitatively similar results. This simulation is based on the point-vortex model, which is a simplified version of the dynamics of a set of vortices.

More precisely, in the point-vortex model that follows, the viscous term is neglected. Thus, this problem aims to mimic in some way the dynamics of the Navier-Stokes equations as $\nu \rightarrow 0$ (or equivalently $\text{Re} \rightarrow \infty$, see Eq. (2.19)). Moreover, the vortices are considered as point-like objects, that is to say, being the vorticity singular at the position of the vortices. Because of that, the vortices are characterized by their circulation

$$\Gamma = \lim_{\text{diam}(\mathcal{C}) \rightarrow 0} \int_{\mathcal{C}} \mathbf{u} \cdot d\mathbf{s} \quad (2.20)$$

where \mathcal{C} is a curve surrounding the vortex. In those conditions and in absence of external forces, the vorticity field ω is only advected and its evolution in time is described by the following transport equation:

$$\partial_t \omega + (\mathbf{u} \cdot \nabla) \omega = 0 \quad (2.21)$$

together with the incompressible condition $\nabla \cdot \mathbf{u} = 0$ (Ceci and Seis 2022). Here \mathbf{u} is the velocity field generated by the vortices. An interesting interpretation of the vortices involves the Dirac's delta distribution. Specifically, the vorticity field generated by a point vortex located at \mathbf{y} can be represented as a distribution of the form:

$$\omega(\mathbf{x}, t) = \Gamma \delta(\mathbf{x} - \mathbf{y}) \quad (2.22)$$

where Γ is the circulation of the vortex (Saffman 1993). The dynamics of N point vortices in the \mathbb{R}^2 plane are described in the following theorem:

Theorem 1. Consider N vortices at positions $\mathbf{z}_1, \dots, \mathbf{z}_N \in \mathbb{R}^2$ and with circulations $\Gamma_1, \dots, \Gamma_N$. Then, their evolution in time is described by the following system of ordinary differential equations (Aref 2007):

$$\dot{x}_i = - \sum_{j \neq i} \frac{\Gamma_j}{2\pi} \frac{y_i - y_j}{(x_i - x_j)^2 + (y_i - y_j)^2} \quad (2.23)$$

$$\dot{y}_i = \sum_{j \neq i} \frac{\Gamma_j}{2\pi} \frac{x_i - x_j}{(x_i - x_j)^2 + (y_i - y_j)^2} \quad (2.24)$$

for $i = 1, \dots, N$, where $\mathbf{z}_i = (x_i, y_i)$.

Proof. Since there is no viscosity in the equations, each vortex is advected with the velocity field generated by all the other vortices. Now, given $\mathbf{f} \in \mathcal{C}^1(\mathbb{R}^2, \mathbb{R}^2)$ and $\mathbf{g} := \nabla \times \mathbf{f}$, by Biot-Savart law one can invert the curl operator using the Biot-Savart kernel (see Griffiths 2023):

$$\mathbf{f}(\mathbf{x}) = (\mathbf{K} * \mathbf{g})(\mathbf{x}) = \int_{\mathbb{R}^2} \mathbf{K}(\mathbf{x} - \mathbf{y}) \mathbf{g}(\mathbf{y}) d\mathbf{y} \quad (2.25)$$

where $\mathbf{K}(\mathbf{x}) = \frac{1}{2\pi} \frac{(-x_2, x_1)}{|\mathbf{x}|^2}$ is the Biot-Savart kernel and $\mathbf{x} = (x_1, x_2)$. In our case, \mathbf{g} is the vorticity field which is a sum of δ 's. Thus, taking into consideration Eq. (2.22), the velocity field generated by a vortex at \mathbf{z}_j with circulation Γ_j is:

$$\mathbf{u}_j(\mathbf{x}) = \mathbf{K}(\mathbf{x} - \mathbf{z}_j) \Gamma_j \quad (2.26)$$

We conclude using the superposition principle. \square

In order to closer the gap between the point-vortex model and the Navier-Stokes equations while keeping the simplicity of the former, an extra equation is added to the pair of equations above. This equation concerns the evolution of the circulations of the vortices. A drag term is added in order to mimic the energy dissipation in the Navier-Stokes equations. The form of the equation is:

$$\dot{\Gamma}_i = -\alpha \Gamma_i \quad (2.27)$$

Another aspect worth-mentioning is the numerical addition of a softening parameter ε to the equation in the form:

$$\dot{x}_i = - \sum_{j \neq i} \frac{\Gamma_j}{2\pi} \frac{y_i - y_j}{(x_i - x_j)^2 + (y_i - y_j)^2 + \varepsilon^2} \quad (2.28)$$

$$\dot{y}_i = \sum_{j \neq i} \frac{\Gamma_j}{2\pi} \frac{x_i - x_j}{(x_i - x_j)^2 + (y_i - y_j)^2 + \varepsilon^2} \quad (2.29)$$

This prevents the positions to blow up when two vortices get too close to each other, which in [Section 3.2](#) is shown to be the common behavior of the system. The softening parameter is chosen to be $\varepsilon = 0.001$, being this value small enough to not affect the dynamics of the system but large enough to prevent a numerical blow-up.

2.5 Monitored quantities

In order to keep track of the evolution of the system, several variables are monitored during the simulation.

For the Navier-Stokes equations, the main quantity of interest is the total energy and vorticity in the system. Since the work environment is the Fourier space (see [Section 3.1](#)), the energy is computed as

$$E = \sum_{\mathbf{k} \in \mathbf{K}} \|\hat{\mathbf{u}}(\mathbf{k})\|^2 = \sum_{\mathbf{k} \in \mathbf{K}} k^2 |\hat{\psi}(\mathbf{k})|^2 \quad (2.30)$$

which by the Parseval identity is equivalent to the total energy in the physical space. Here $\mathbf{K} = \{0, 1, \dots, K-1\}^2$ is the set of points in the Fourier grid, and $K = N/3$ is the maximum wave number chosen in order to control the aliasing effects. Another important quantity worth-considering is *enstrophy*, which is analogous to energy but uses vorticity instead of velocity as the primary variable. It is defined as

$$\Omega = \sum_{\mathbf{k} \in \mathbf{K}} |\hat{\omega}(\mathbf{k})|^2 = \sum_{\mathbf{k} \in \mathbf{K}} k^4 |\hat{\psi}(\mathbf{k})|^2 \quad (2.31)$$

where the second equality follows from the relation $\omega = -\Delta\psi$.

As the title suggests, the main purpose of this work is to study how turbulence is spread across the system. Thus, quantities relating the energy (and enstrophy) contained in rings as a function of the radius are also monitored. We denote these variables as E_k and Ω_k respectively, and they are given by the following expressions:

$$E_k = \sum_{k-1 < \|\mathbf{k}\| \leq k} \|\hat{\mathbf{u}}(\mathbf{k})\|^2 \quad (2.32)$$

$$\Omega_k = \sum_{k-1 < \|\mathbf{k}\| \leq k} \|\hat{\omega}(\mathbf{k})\|^2 \quad (2.33)$$

where $k \in \{1, \dots, K\}$. The quantities E_k and Ω_k are then plotted as a function of k in order to study the energy and enstrophy distribution across the system (see [Section 3.2](#)).

Related to those two latter variables is the mean energy radius and mean enstrophy radius, which refer to an weighted average of the radius where most of the energy (and enstrophy, respectively) is contained. They are defined as

$$\mathcal{R}_E = \frac{\sum_{k=1}^K k^2 E_k}{\sum_{k=1}^K E_k} \quad (2.34)$$

$$\mathcal{R}_\Omega = \frac{\sum_{k=1}^K k^2 \Omega_k}{\sum_{k=1}^K \Omega_k} \quad (2.35)$$

Note that since the domain is square, the sums $\sum_{k=1}^K E_k$ and $\sum_{k=1}^K \Omega_k$ are slightly less than the total energy E and enstrophy Ω respectively, since they count the contribution of the different rings in the domain up to the incircle of the square.

Regarding the point-vortex model, the system is integrable and the following function H

$$H = \sum_{i=1}^N H_i, \quad H_i = -\frac{1}{4\pi} \sum_{j \neq i} \Gamma_j \log \|z_i - z_j\|^2 \quad (2.36)$$

is a first integral of the system. Moreover the system is Hamiltonian, that is, it can be written as:

$$\dot{x}_i = \frac{\partial H}{\partial y_i} \quad (2.37)$$

$$\dot{y}_i = -\frac{\partial H}{\partial x_i} \quad (2.38)$$

At first sight, the reader may notice that function H is singular when two vortices get too close to each other. Although one could try to create a function $f(H)$ that is regular in the whole domain and has a shape according to the physical intuition while keeping the properties of a first integral, in this work we opted for another approach to mimic the energy and enstrophy profiles for the Navier-Stokes equation.

The idea explored here relies on counting the number of point vortices in rings and compare the density distribution with the respective functions E_k and Ω_k , once transformed back to the physical space.

3 Simulation

3.1 Numerical setup

The 2D incompressible Navier Stokes equations are forced in a periodic domain of size $2\pi \times 2\pi$ with a forcing term that is located in a disk of radius π/k_r centered at the origin. The range of values for the parameter k_r is taken to be $\{8, 16, 32, 64\}$ and in all the cases the size of the vortices, which is controlled by k_ℓ , is set to $k_\ell = 4k_r$. The parameter k_r being one of those values in the previous set represents how smaller is the perturbation region (in diameter) compared to the domain size (2π). The other parameter k_ℓ accounts for the number of vortices introduced in the domain, when there are no other vortices traveling in the domain. In those conditions, $(\pi k_\ell^2)/(\pi k_r^2) = 16$ vortices are introduced in the domain (see Fig. 1).

Figure 1: Forcing term for different values of k_r . Red colors and blue colors mean different direction of rotation for each vortex. The reader may notice that indeed the diameter of the forcing region is about 8 times smaller than the total size of the domain. In the second plot, this property is less noticeable, but it is still true, this case 64 times smaller. In the second plot, the colors have been enhanced to make the plot more clear.

The Reynolds number is the other parameter that plays an important role in the whole simulation. This project has simulated fluid flows for Reynolds numbers within the set $\{0.25, 0.5, 1, 2, 4, 8, 16, 32, 64, 128\}$, each of those requiring different resolution as we increase the Reynolds number.

A pseudo-spectral method has been used to solve the Navier Stokes equations, based on the Fourier basis and then using a 4th-order low-storage Runge-Kutta method to integrate the resulting ordinary

differential equation. As explained in Brachet et al. 2008, this method differs from the conventional one in the . For more information, the reader is encouraged to read the article from Brachet et al. 2008 or check the source codes in the link provided below.

The codes have been run in a cluster with 40 to 80 cores, owned by IDRIS² and MESOPSL³, depending on the simulation. Two different kinds of simulations have been performed: parallel simulations and embarrassingly parallel simulations. In the parallel simulations, the Fourier domain is divided among all the processors, allowing them to work simultaneously on different parts of the problem. In the embarrassingly parallel simulations, each simulation runs independently on a single core. Multiple simulations are executed concurrently, one on each available core, and the results are averaged afterward to obtain more accurate conclusions. Details about the parallelization of the code will not be delved into, but in brief... If the reader is interested in the details, the article from Mininni et al. 2011 is highly recommended. For the parallel code, a variable time step is used throughout the whole simulations in order to take into account the advection stability condition. For the embarrassingly parallel code, a fixed time step is used, in order to better compare the results between the different runs from the same simulation. The time step is chosen by eye after studying the evolution of the time steps during the parallel simulations. Table 1 shows the different simulations performed during the project as well as the resolution in physical space used in each case.

$k_r \backslash \text{Re}$	0.25	0.5	1	2	4	8	16	32	64	128
8	✓ ₅₁₂	✓ ₅₁₂	✓ ₅₁₂	✓✓ ₅₁₂	✓✓ ₁₀₂₄	✓✓ ₁₀₂₄	✓✓ ₁₀₂₄	✓✓ ₂₀₄₈	✓ ₂₀₄₈	✓ ₄₀₉₆
16				✓ ₁₀₂₄	✓ ₂₀₄₈	✓✓ ₂₀₄₈	✓✓ ₂₀₄₈	✓✓ ₂₀₄₈	✓ ₄₀₉₆	✓ ₄₀₉₆
32				✓ ₂₀₄₈	✓ ₄₀₉₆	✓✓ ₄₀₉₆	✓✓ ₄₀₉₆	✓✓ ₄₀₉₆	✓ ₈₁₉₂	✓ ₈₁₉₂
64						✓ ₈₁₉₂	✓ ₈₁₉₂	✓ ₈₁₉₂		

Table 1: Simulations performed during the project varying the Reynolds number and the forcing parameter k_r . The green check mark symbols indicate the simulations done in parallel, splitting the domain between different cores. The blue check mark symbols indicate the simulations done in embarrassingly parallel, where each simulation is done in a single but in many cores at the same time in order to produce statistics results. In each cell, the number indicates the resolution in each dimension employed, which have been proved (a posteriori) to be enough to well-resolve the system.

The reader may observe that the resolution increases both as the Reynolds number and the forcing parameter k_r increase. For the former, the resolution is increased in order to resolve the smaller scales that appear in the system. For the latter, the resolution is increased to resolve the smaller perturbation region.

It is worth-noting that the resolution in Fourier space is not the same as the one in physical space.

All the codes and data used for the simulations are available in the following repository: <https://github.com/victorballester7/final-master-thesis> (accessed on June 30, 2024).

3.2 Results

4 Conclusions

Acknowledgements

I would not like to finish this project without thanking the people who have helped me along the way. First and foremost, I would like to thank my two supervisors, Prof. Alexandros Alexakis and Prof. Emmanuel Dormy, for their guidance and constant support throughout the project. This project was, in the theoretical perspective, a bit far from my previous works, but their continuous help and advice made it possible. I would also like to thank the whole group led by Professor Stéphan Fauve in the Laboratoire de Physique de l'École Normale Supérieure, for giving me a desk and a place to work during
